

How fast does politics move a stock exchange?

Calibrating the magnitude of political shocks at the Bucharest Stock Exchange, 2020–2026

September 2026

Abstract

Question. How fast, and how strongly, do shares on the Bucharest Stock Exchange react to political news? We apply an event study to 24 events over 2020–2026, using daily quotes for the BET index, 8 liquid stocks and 4 complementary indices, plus 15-minute bars around the three major electoral shocks.

Speed. The response forms at the open of the first session after the event. In November 2024 the lowest 15-minute bar came 15 minutes after the open.

Magnitude, in two senses. Calibrated with a placebo test of 500 pseudo-events run through an identical estimator, the null distribution of three-day cumulative abnormal returns has $\sigma = 1,94\%$ and a 95th percentile of 3,98%, so a 3% move over three days occurs in roughly 10,2% of windows drawn from sessions with no political news at all. Read one event at a time, three of the 23 testable events clear the 5% threshold, the second-round presidential victory being the clearest. Read in aggregate, political events do depart from ordinary noise: mean absolute movement is 2,00% on event days against 1,38% on ordinary days, $p = 0,026$ in a permutation test.

Robustness. Re-running the placebo test with four estimation windows, from 40 to 250 sessions, leaves the conclusion unchanged but not the details: the lowest rank correlation across windows is 0,958 and the count of events at $p < 0.05$ moves between 4 and 6. Restricting the null to the post-COVID regime gives a 95th percentile of 4,00%, essentially the full-period value, so the fat tails are not an artifact of the pandemic.

Recovery and tradability. All 100% of political drops of at least 1% return to the pre-shock close within 60 sessions, and so do 89% of random drops of matched depth, a median 12,5 sessions *faster* on the control side and not significantly (1,00, 4 pairs). The opening gap absorbs 59–98% of the three-day move, and the best of 12 pre-declared rules earns 0,41% gross but $-0,09\%$ net at 50 basis points, with breakeven at 41 basis points.

Methodological contribution. Three of the most eye-catching results of an ordinary event study turn out to be measurement failures rather than market phenomena. A fixed estimation window that lands in a calm regime inflates every t -statistic at once. The public BVB feed's adjustment flag does not correct for dividends, so ex-dividend windows are contaminated. A market control estimated in calm conditions can turn a global crash day into a fictitious domestic effect.

1 Data and method

1.1 Quotes

The Bucharest Stock Exchange publishes no developer API, but its website runs a TradingView-compatible datafeed at <https://wapi.bvb.ro/api> that answers plain HTTP requests. The parameters are `symbol`, `from`, `to`, `rs`, `ajust`, `countback` and `currencyCode`, and the daily resolution must be requested as `rs=1D`. We downloaded daily bars in RON for 1 January 2020 to 28 September 2026: the BET index, 8 liquid stocks (TLV, SNP, BRD, H2O, SNG, DIGI, TEL,

SNN) and 4 complementary indices (ROTX, BET-TR, BET-FI, BET-NG), about 1,690 sessions per symbol. H2O enters the series only in July 2023, with the largest IPO in the exchange’s history. For the speed analysis we also downloaded 15-minute bars for BET and TLV around the three major shocks.

One limitation of the source changes the results, so we state it here. The `ajust` flag corrects stock splits but not dividends, and the check is direct: TLV’s return on 11 June 2024, -4.69% , is identical in the adjusted and unadjusted series. Price returns are therefore contaminated in ex-dividend windows, and the Romanian banks’ dividend season, in June, falls in the middle of the window we analyse. The primary series is accordingly **BET-TR**, the exchange’s total-return index, which is immune to this effect. In parallel, the pipeline flags any event where the gap between BET and BET-TR exceeds one percentage point over the same window.

1.2 Benchmark and events

As a model of the European market we used STOXX Europe 600, downloaded daily from Yahoo Finance’s public chart interface and aligned to the exchange’s calendar by forward-filling the last available value.

Articles from the RSS feeds of G4Media, HotNews, Digi24 and Economica were collected automatically and keyword-filtered for political content. RSS covers only the present, so the historical base is a table of 24 manually dated events, each with a confidence level and an *ex-ante* classification of origin (domestic, external, market) and expected direction. Table 7 lists them.

1.3 Estimator

The estimation window is $[-60, -11]$ trading days, truncated at the start of the series, with a minimum of 30 observations. Event windows are $[0, 0]$, $[-1, +1]$ and $[-5, +5]$. For BET and the indices the abnormal return is $AR_t = R_t - \bar{R}_{est}$. For the individual stocks we use an OLS market model against BET, and for the external control an OLS model of BET against STOXX 600, both estimated over the estimation window. The conventional statistic is $t = CAR/(\hat{\sigma}\sqrt{T})$.

Day 0 is the session in which the news appears if that falls before 18:00, and the next trading session otherwise. Every ballot was held on a Sunday evening, so day 0 is the Monday and the opening price carries the full weekend information.

1.4 Placebo calibration

The t -statistics above assume normally distributed, independent returns with volatility measured over the estimation window. On a small and illiquid market that assumption is problematic: a fixed window of 50 sessions can land in a calm regime and understate the volatility used as the denominator. To remove the dependence on a parameter we chose ourselves, we calibrate with a placebo test. We draw 500 pseudo-random trading sessions, excluding three sessions either side of every real event, and apply the identical estimator. The resulting distribution shows how large an ordinary CAR is at BVB, and each real event receives a two-sided empirical p -value on $|CAR|$.

Two further tests follow from the same null. The aggregate test asks whether mean absolute movement is larger on event days than on ordinary days, which sidesteps the multiple-comparisons problem of examining 23 events individually. The window-sensitivity test re-runs the whole calibration under four different estimation windows, which addresses the paper’s own objection that a fixed window may be unrepresentative.

2 Results

2.1 Speed: the response forms at the open

Table 1 and Figure 1 summarise the 15-minute bars. On 25 November 2024 the opening gap was -1.57% , the lowest 15-minute bar, -1.84% , was reached at 10:15, and the close recovered to -0.89% . On 5 May 2025 the -2.13% opening gap deepened continuously into the close. On 19 May 2025, in the positive direction, almost the entire gain formed at the open.

Table 1: Speed of the intraday response of BET, from 15-minute bars.

Shock	Opening gap	Intraday low (local)	Close	Pattern
Presidential first round 2024	$-1,57\%$	$-1,84\%$ (10:15)	$-0,89\%$	instant shock, partial recovery
Presidential first round 2025	$-2,13\%$	$-2,88\%$ (17:45)	$-2,88\%$	degraded all day
Presidential second round 2025	$4,12\%$	$3,62\%$ (12:30)	$4,08\%$	instant gain

Figure 1: Intraday response to the first round of May 2025. BET and TLV rebased to the close before the shock.

2.2 Who reacts hardest

Table 2 compares the indices over the three-session window. ROTX reproduces BET, which rules out a construction artifact in the index. Financials amplify the May 2025 panic at -4.51% against BET, while energy damps systematically, at -2.82% against -3.50% . At the level of individual stocks, banks absorb the first blow: TLV fell -4.11% on 5 May 2025, against -2.88% for BET.

Table 2: $CAR[-1, +1]$ across indices, in percent. The primary series is BET-TR.

Event	BET-TR	ROTX	BET-FI	BET-NG
Presidential first round 2024	$-1,60$	$-1,28$	$0,03$	$-0,90$
Parliamentary elections 2024	$-3,74$	$-3,58$	$-3,55$	$-2,87$
Constitutional Court annulment 2024	$4,34$	$4,21$	$1,90$	$3,67$
Presidential first round 2025	$-3,50$	$-3,32$	$-4,51$	$-2,82$
Presidential second round 2025	$6,94$	$6,88$	$5,14$	$6,13$

Figure 2: $CAR[-1, +1]$ across the indices for the five major shocks.

2.3 The large electoral shocks are domestic

On the key days STOXX Europe 600 is close to flat: +0.06% on 25 November 2024, +0.16% on 5 May 2025 and +0.13% on 19 May 2025. On those same days BET records -0.89% , -2.88% and $+4.08\%$. The divergences are domestic. We note that this rests on the raw comparison rather than on the model residual, for reasons given in Section 5.

Figure 3: BET and STOXX 600, base 100 at the start of 2020. Vertical lines mark high-confidence political shocks.

2.4 Calibrating the magnitude

The placebo test recalibrates the reading of everything else. The null distribution of $CAR[-1, +1]$ has a mean of -0.002% and $\sigma = 1.94\%$, with $|CAR_3|$ at the 95th percentile of 3.98% and a maximum of 9.81% . A 3% move over three sessions occurs in 10.2% of the 500 pseudo-event windows drawn from sessions with no political news at all, so the effective detectability threshold for a political event is of order 4%.

Table 3: Placebo test: $CAR[-1, +1]$ on BET-TR against the null distribution.

Event	CAR_3	conventional t	empirical p	Placebo verdict
Presidential second round 2025	6,94	3,58**	0,014	clears the null
Constitutional Court annulment 2024	4,34	3,91**	0,038	clears the null
Fitch outlook to negative 2024	-4,31	-3,10**	0,040	clears the null
Parliamentary elections 2024	-3,74	-3,71**	0,066	marginal
Ciolacu resignation 2025	-3,50	-1,80	0,076	marginal
Presidential first round 2025	-3,50	-1,80	0,076	marginal
Ciolacu II government formed 2024	2,97	1,82	0,108	not significant

Of the 23 of 24 political events that have a full estimation window, three clear the 5% threshold: the second-round presidential victory in May 2025 at 6,94% and $p = 0,014$ (percentile 98,8), the Constitutional Court’s annulment of the election at 4,34% and $p = 0,038$, and the Fitch outlook revision at $-4,31\%$ and $p = 0,040$. The December 2024 parliamentary elections sit at $p = 0,066$, inside the ordinary range, though the conventional t -test would have reported them as significant. The earliest event, the March 2020 state of emergency, falls inside the first 60 sessions and cannot be estimated; it is the largest single move in the sample, so the exclusion works against the result rather than for it.

Read one event at a time, that is a thin result. Read in aggregate, the effect is there. Per-event tests suffer from multiple comparisons, and with 23 events at a 5% threshold roughly one would clear by chance. The aggregate test asks the question directly, whether mean absolute movement is larger on event days. Across the 22 distinct event sessions, mean $|CAR|$ is 2,00% against 1,38% on sessions without an event. Compared through 20000 random draws from the null, the difference has $p = 0,026$. 3 events pass the 95th percentile against 1,1 expected from chance alone. Political news produces larger movements than background noise, and the error margin on any single event is too wide to separate it from noise.

Figure 4: Absolute movement on political event days against the null distribution of non-event sessions.

2.5 Sensitivity to the estimation window

The window $[-60, -11]$ was an arbitrary choice, and the whole problem identified above stems from its possibly landing in an unusual regime. Table 4 re-runs the complete placebo test with

four windows, from 40 to 250 sessions before the event. Only 19 of the 23 events have enough history for the longest of them.

Table 4: Placebo results by estimation window.

Estimation window	n	$p < 0,05$	Events
$[-250, 9]$	19	6	Presidential second round 2025, Constitutional Court annulment 2024, Fitch outlook to negative 2024, Parliamentary elections 2024, Ciolacu resignation 2025, Presidential first round 2025
$[-120, 9]$	19	4	Presidential second round 2025, Constitutional Court annulment 2024, Fitch outlook to negative 2024, Parliamentary elections 2024
$[-60, 9]$	19	4	Presidential second round 2025, Constitutional Court annulment 2024, Fitch outlook to negative 2024, Parliamentary elections 2024
$[-40, 9]$	19	4	Presidential second round 2025, Constitutional Court annulment 2024, Fitch outlook to negative 2024, Parliamentary elections 2024

The conclusion does not depend on the window, but the fine detail does. The lowest rank correlation across the four windows is 0,958, so the ordering is close to but not exactly stable. The count of events at $p < 0.05$ rises from 4 on the shortest window to 6 on the longest, driven by the null’s 95th percentile, which moves from 3,65% to 3,43%. A reader who wanted the shortest count could take the shortest window and a reader who wanted six could take the longest. That the two ends of the range both include the May 2025 run-off, the court annulment and the Fitch revision is the robust part; the exact count is a property of the calibration rather than of the data. Restricting the calculation to the post-COVID regime gives a 95th percentile of 4,00%, so the fat tails are not an artifact of the pandemic.

One confound belongs here rather than in a footnote. The longest window needs 250 sessions of history, so its null is built from sessions that all postdate the 2020 crash, and its 95th percentile is therefore lower partly because the sample excludes the volatility of the pandemic and not only because the window is longer. The four percentiles above are not comparable to each other with total precision, and we would rather say so than attribute the whole movement to the window.

2.6 Group statistics, reported as description

Mean $CAR[-1, +1]$ across domestic news with an expected negative sign is $-1,00\%$ over 7 events, and $-2,94\%$ for the 2024–2025 electoral trio. We report both as description of the class rather than as inference, because the expected-sign labels were assigned by the researcher with knowledge of the outcomes, so any test built on that classification is circular by construction.

Anticipated events do not move the market. The 2021 no-confidence motion that ousted the CiÊledilău government with 281 votes, the largest such vote in the country’s history, leaves a CAR of -0.19% . The December 2020 parliamentary elections, in which AUR surprised, leave -0.18% . In both cases the outcome was public before voting day.

3 How long does the recovery take?

The obvious next question is whether the damage is temporary, and the market does come back. That observation is not evidence of anything, for the same reason the placebo test was needed above: random drops of the same depth also come back.

For each political drop of at least 1% we count the trading days until the close returns to its pre-shock level. Each event is compared with a matched control sample of random drops whose depth falls within a tolerance of that event’s own depth, so the comparison does not depend on how depths are distributed across events. The control pool excludes sessions within three days of any real political event and no drop is drawn twice, so the controls are independent of the events they are meant to contrast with.

Table 5: Recovery after political shocks of at least 1%.

Event	Day 0 move	Days to recover	Further decline
COVID state of emergency	−9,58%	16	−1,22%
Russian invasion of Ukraine	−4,09%	37	−13,40%
Presidential first round 2025	−2,88%	10	−1,93%
Fitch outlook to negative 2024	−2,30%	32	−2,00%
Bolojan government formed 2025	−1,18%	6	−0,45%
Local + European elections 2024	−1,14%	6	−0,13%

Recovery is universal, and it is equally universal for drops with no political news attached. All 100% of political drops of at least 1% return to the pre-shock close within 60 sessions, and 89% of the matched random drops do the same. On time to recovery the paired difference is 12,5 sessions in favour of the control sample, so political shocks recover if anything more slowly. Across the 4 usable pairs they recover faster in 2, and the permutation test gives no support for faster recovery. With 4 pairs this test has almost no power, which is itself the point: the sample is too small to distinguish the two distributions.

The reason is the sample period. BET-TR rose substantially over 2020–2026, which makes “back to where it was” a low bar, and a low bar says nothing about panic. The two shocks with the longest recovery are the two where the market kept falling afterwards, which is precisely when buying the dip would have hurt.

Figure 5: Time to recovery of the pre-shock close, political shocks against random drops of matched depth.

4 Is the effect tradable?

4.1 Little is left after the news is public

The opening gap absorbs between 59% and 98% of the three-day cumulative abnormal return around each major shock. What remains for someone who reacts to the news, after it is published and the price has already moved, is between 0,03% and 2,82% in absolute terms. A rule that reacts to news trades the remainder. A rule that would profit has to hold a position from before the event, which is a forecasting problem, and this study contains no evidence about it, since election outcomes are settled after the vote.

4.2 The gross edge is smaller than the cost of trading

We declared twelve candidate rules in advance and split the sample chronologically into 11 train and 13 test events. One of the twelve is an overlay that takes no position at all, so the max statistic that pays for the search is taken over the remaining 11 rules. The best rule (*openshortall*) earns 0,41% per trade gross and $-0,09\%$ net at 50 basis points.

Table 6: Net return per trade for the best rule, by transaction cost.

Round-trip cost	Net return per trade
0 bps	0,41%
25 bps	0,16%
50 bps	$-0,09\%$
100 bps	$-0,59\%$
200 bps	$-1,59\%$

Breakeven sits at 41 basis points, interpolated between the two cost levels that straddle the crossing. Commission, spread and market impact on a market this illiquid plausibly run at 50 to 200 basis points in each direction, and we did not measure them; if that range is wrong the verdict changes, which is why the verdict rests on the cost table rather than on any single number. The chance of finding something that looks significant by luck alone across 11 attempts is 43%.

The reality check on the max statistic returns $p = 0,942$, and we report it with a caveat that matters more than the number. The best observed t across the tradable rules is negative, so every null draw beats it by construction and the test has no power to reject anything. What it does not say is that the rules are indistinguishable from noise; it says that no rule has a positive expected return after costs, which the cost table already establishes directly. A reality check earns its keep when some rule looks good, and that is exactly the case that does not arise here.

4.3 The constraint is the sample, not the search

With $n = 24$ events, a per-trade standard deviation of 2,19% and a standard error of 0,45%, the minimum detectable effect at 5% significance and 50% power is 0,88% per trade. Reaching 80% power at that effect would need roughly 227 events, about nine times what the period contains. A Romanian electoral cycle offers two or three rounds a year and the useful measurement window is one to three sessions, so this design yields tens of events, not hundreds.

An effect of this size would therefore not be visible at this sample size, whether or not it exists. More rules cannot fix that. Only more events can.

4.4 One loose thread

The rule entering at the open of the event day outperformed the rule entering a session earlier, and the two differ only in the session before the event. That implies the average pre-event session was slightly positive, of order 0.2%, which would be a small anticipatory drift rather than a news-trading effect. At 24 events this is indistinguishable from noise and we leave it unresolved. It is the one finding here that a prospective register could test and a retrospective sample cannot.

5 Three results that turned out to be measurement failures

The three most striking results of the analysis are not market phenomena.

5.1 The CiucÄf government: a global selloff day

The 25 November 2021 event shows a CAR of $-2,60\%$ with $t = -3,02$, among the largest in the table. The raw path shows otherwise. 26 November 2021 was the global selloff triggered by the

designation of the Omicron variant, with STOXX 600 at $-3,67\%$ and BET at $-3,41\%$, closing at the low of the day. BET fell less than Europe. The investiture day itself was positive, at $0,57\%$. Volumes confirm a market-wide move: TLV at 4.09 million shares against roughly 1.6 million previously, BRD at 175,000 against about 69,000, SNG at 180,000 against about 14,000.

The -2.04% residual reported as a STOXX-adjusted effect is an artifact of beta instability. The beta the model estimates on its own 50-session window is 0,16; re-estimated on the 50 sessions after the event it is 0,38, and on the shock session itself the two indices moved almost one for one, BET at $-3,41\%$ against STOXX at $-3,67\%$. The model therefore predicts a small BET decline, BET falls almost in line with Europe, and the model books a fictitious domestic shortfall. A market control is not conservative by construction. Any check of an effect’s domestic origin has to compare raw returns with STOXX, not only the model residual. The explanation we initially entertained, that the market taxed the grand coalition, has no support: such a tax would have appeared on the investiture day, which was positive.

5.2 June 2024 elections: dividend season

The event shows $-3,01\%$ with $t = -3,49$. On total returns the same event is $-0,59\%$. The cause is the banks’ ex-dividend season, which falls exactly in the event window. The pipeline flags this type of contamination automatically and flags no other event in the series. Unlike the case above, this is a limitation we could act on: the event is excluded from the group test, and doing so changes nothing that follows. It remains in the per-event and aggregate sets, where its p -value is large and it changes nothing there either.

5.3 The court annulment: a rebound that had already started

The Constitutional Court’s decision of 6 December 2024 shows $+2,97\%$ on day 0 and $4,34\%$ over three sessions, with one of the largest t -statistics in the table. The rebound had begun on 4 December, two sessions before the decision: BET traded -3.24% intraday, then reversed violently and closed green. The estimation window ends around 19 November and does not contain the late-November decline, so a stale baseline reads the post-crash rebound as a positive abnormal return. Unlike the dividend case we cannot drop this event without changing the headline result, so we keep it in every set and flag it. It is one of the three events that clear the threshold, and its $p = 0,038$ should be read as conditional on a baseline that we can show to be stale.

6 Limitations

There are 24 manually dated events, and the calibration above puts the detection threshold at of order 4% over three sessions, so this design cannot settle many further questions about such effects. The number of events reaching 5% varies between 4 and 6 with the estimation window, though the same three clear it at every window. We report the range rather than pick a window. No official total-return series exist for the individual stocks, so BET-TR covers the index only and dividend contamination remains possible at the stock level. BET’s composition changes over time and the basket used here is fixed. RSS covers only the present, so the historical base depends on manual dating, and two events carry medium confidence. BVB is illiquid, so the intraday inference rests on high-turnover sessions.

External validation is partial and we state the limits. The daily data reproduce the reported closes: BET at 16,982 points and -0.89% on 25 November 2024 [2], and -0.45% where the press reports “about half a percent” on the second day in May 2025 [3]. The intraday figure of -1.69% [3] cannot be checked against our data, because the feed returns closing prices per 15-minute bar rather than intrabar extremes; our lowest bar that day is -2.88% , so the reported low is not contradicted but not confirmed either.

7 Conclusion

Romanian politics moves BVB fast, and the market does recover from the resulting drops. But recovery is not a reason to buy, since random drops of the same depth recover in slightly less time, and the gross edge is smaller than the cost of trading. The effect is real in aggregate and unexploitable in practice, which is the honest description of a market this small and this illiquid rather than a failure of the study.

One methodological failure is worth recording for anyone repeating this work, because it cut in the flattering direction. Costs were originally subtracted with the sign of the position, so a short was credited the transaction cost instead of paying it and short returns rose as costs rose. The same rule that looked like a thin positive margin net of 50 basis points loses money once the sign is corrected. A cost error of this kind is invisible in the gross numbers and surfaces only when the cost parameter is varied.

What the sample cannot do is settle the question. The remedy is a prospective register: fix a rule, record each shock together with the news that arrived with it, and fill in the outcome only afterwards. The accompanying code implements one, writing each detection to a log before the outcome is known, so that a few years of accumulation could settle what 24 retrospective events cannot. The code, the data, the placebo test and the figures are available for replication and extension.

A The event set

Table 7: Events in the input table.

Event	Type	Day 0	Confidence
